Kin selection theory predicts that, where kin discrimination is possible, animals should typically act more favorably toward closer genetic relatives and direct aggression toward less closely related individuals. Contrary to this prediction, we present data from an 18-y study of wild banded mongooses, *Mungos mungo*, showing that females that are more closely related to dominant individuals are specifically targeted for forcible eviction from the group, often suffering severe injury, and sometimes death, as a result. This pattern cannot be explained by inbreeding avoidance or as a response to more intense local competition among kin. Instead, we use game theory to show that such negative kin discrimination can be explained by selection for unrelated targets to invest more effort in resisting eviction. Consistent with our model, negative kin discrimination is restricted to eviction attempts of older females capable of resistance; dominants exhibit no kin discrimination when attempting to evict younger females, nor do they discriminate between more closely or less closely related young when carrying out infanticidal attacks on vulnerable infants who cannot defend themselves. We suggest that in contexts where recipients of selfish acts are capable of resistance, the usual prediction of positive kin discrimination can be reversed. Kin selection theory, as an explanation for social behavior, can benefit from much greater exploration of sequential social interactions.

kin selection | kin discrimination | conflict | cooperation | eviction

Kin selection theory aims to understand how selection acts on social traits, such as altruism and selfishness, that affect the fitness of social partners and local group members (1, 2). The theory predicts that where animals can discriminate between more closely and less closely related individuals within their social group, they will preferentially direct altruism toward closer genetic relatives and aggression toward less closely related targets (1–3). Instances of such positive kin discrimination are taxonomically numerous and widespread (4), whereas reported examples of negative kin discrimination are rare (5, 6).

Contrary to the predictions of traditional kin selection theory, we show below that banded mongooses exercise negative kin discrimination during attempts at eviction and that this result is not readily explained by inbreeding avoidance or local kin competition. However, a simple and very general sequential game model of selfish behavior that takes into account the possibility of active resistance on the part of recipients does provide a potential explanation for negative kin discrimination. We first describe the model and then test predictions of the model using our data.

Explaining Negative Kin Discrimination: A Model

Consider the interaction between two individuals, the first of whom (player 1) may perform a selfish act at the other's expense, such as stealing a food item, killing offspring, or, in the case with which we are concerned, evicting the other from the territory or group. We suppose that this act entails some fitness cost to the

actor, denoted c_1 , but that the cost is outweighed by the benefit to be gained, $b_1 > c_1$. The act, if carried out, also deprives the recipient, player 2, of a benefit b_2 that it would otherwise enjoy. If the two individuals are related by a coefficient r , then Hamilton's rule tells us that the act will be favored by selection provided that $b_1 - c_1 - r b_2 > 0$. Consequently, selfishness will never be directed toward a closer relative where it would not also be directed toward a more distant one.

Suppose, however, that if player 1 attempts the selfish act, player 2 may then choose to resist. Resistance ensures that the act will fail; player 1 will still suffer the cost c_1 of attempting the act, but will not enjoy the benefit b_1 of success, nor will player 2 suffer the consequent loss of benefit b_2 . At the same time, resistance entails a fitness cost to player 2 of c_2 . This situation may be modeled as a two-step, sequential game, as illustrated in Fig. 1 (see *SI Models* for a population genetic formulation of the model; Fig. S1).

How does relatedness affect the outcome of this game? Applying Hamilton's rule once again, if $c_2 > b_2 - r b_1$, then the cost of resistance to player 2 outweighs the benefit of preventing a selfish act. Under these circumstances, player 2 will submit, and selection once again favors performance of the selfish act provided that $b_1 - c_1 - r b_2 > 0$. If, by contrast, $c_2 < b_2 - r b_1$, then player 2 will resist, and selection consequently does not favor the selfish act. Because a more closely related recipient of the selfish act may prefer to submit where a more distantly related recipient would resist, it follows that selfishness may

Significance

Kin selection theory predicts that animals will direct altruism toward closer genetic relatives and aggression toward more distantly related individuals. Our 18-y study of wild banded mongooses reveals that, unusually, dominant individuals target females who are more closely related to them for violent eviction from the group. This puzzling result can be explained by selection for unrelated individuals to resist eviction and for related individuals to submit more easily. In support of this idea, we show that kin are targeted for aggression only when individuals are capable of resisting. Our results suggest that, where potential victims can oppose aggression, the usual predictions of kin selection theory can be reversed.

Fig. 1. A sequential model of selfishness and resistance. Player 1 (blue) first chooses whether or not to attempt a selfish act at the expense of player 2 (red); in the event of such an attempt, player 2 then chooses whether or not to resist. Direct fitness payoffs to both players are shown in their respective colors.

be directed toward a closer relative where it would not be directed toward a more distant one. To be precise, if we consider two levels of relatedness, r_{high} and r_{low} ($r_{\text{low}} < r_{\text{high}}$), then provided that

$$\frac{b_1 - c_1}{b_2} > r_{\text{high}} > \frac{b_2 - c_2}{b_1} > r_{\text{low}},$$

then the subgame-perfect equilibrium of the game features targeting of a selfish act toward a recipient related to the actor by r_{high} , but not toward a recipient related by r_{low} . To illustrate, suppose $b_1 = b_2 = 1$, $c_1 = 0.25$, and $c_2 = 0.75$; then the model predicts that a recipient of low relatedness ($r_{\text{low}} < 0.25$) would resist a selfish act and hence should not be targeted, whereas a recipient of higher relatedness ($0.75 > r_{\text{high}} > 0.25$) will submit and so should be targeted.

Unrelated recipients are more likely to resist a selfish act, favoring preferential targeting of more closely related victims, when c_2 (the cost of resistance) is small and b_2 (the benefit to be retained) is large. These effects are illustrated in Fig. 2. If c_2 is typically too large, or b_2 too small, even unrelated recipients are unlikely to resist, favoring indiscriminate selfishness; only for smaller values of c_2 or larger values of b_2 is negative kin discrimination predicted.

Negative Kin Discrimination in Banded Mongooses

We examine kin discrimination in the context of a conspicuous form of intragroup aggression in cooperatively breeding banded mongooses, *Mungos mungo*: the violent eviction of males and females from the group. Banded mongooses live in highly cooperative groups with limited dispersal and varying levels of relatedness between group members (7). In our study population in Uganda, groups consist of around 20 adults, plus offspring, and breed on average four times per year (8). Multiple females give

birth synchronously to a communal litter that is cared for by members of both sexes (typically not the parents) (7). Each group contains a cohort of multiple dominant females (median = 4) that are older than the other females, breed more regularly and more successfully, and aggressively evict younger females (7, 9, 10). Older males monopolize mating with estrus females by mate guarding them and aggressively driving away younger, subordinate males (10, 11). Previous work shows that both sexes are capable of kin discrimination in the context of mating, supporting the assumption of our model that such discrimination is possible in this system (12). Evictions are relatively common, involve intense, targeted aggression, and result in the forcible mass exclusion of groups (median = 6 individuals) of females (female-only evictions) and, in around half of cases, groups (median = 9 males) of males alongside them (mixed-sex evictions) (13). These mass evictions are triggered by high levels of intrasexual reproductive competition: females are evicted when there are many breeding females in the group, and males are evicted alongside females when there are many breeding males (13). Evictions are very violent, and evictees are often left with serious injuries as a result of the aggression they receive (Movie S1).

Among adult female banded mongooses, those more closely related to dominant individuals of both sexes (that is, males and females older than 3 y) in the group were more likely to be targeted for eviction [generalized linear mixed model (GLMM), $\beta \pm \text{SE} = 9.95 \pm 3.36$, $\chi^2_1 = 9.51$, $P = 0.002$; Fig. 3A and Table S1]. Younger females were also more likely to be subject to an eviction attempt (GLMM, $\beta \pm \text{SE} = -0.003 \pm 0.0005$, $\chi^2_1 = 39.98$, $P < 0.0001$; Table S1), but there was no effect of a female's pregnancy status or nonpregnant weight on her probability of being targeted for eviction (pregnancy status, GLMM, $\beta \pm \text{SE} = -0.61 \pm 0.49$, $\chi^2_1 = 1.63$, $P = 0.20$; weight, GLMM, $\beta \pm \text{SE} = 0.002 \pm 0.001$, $\chi^2_1 = 2.59$, $P = 0.11$; Table S1). For a subset of eviction attempts we had data on the identity of "primary aggressors" (individuals that were recorded as being notably more aggressive than other group members toward potential evictees). Females that were more closely related to primary aggressors were more likely to be targeted for eviction (GLMM, $\beta \pm \text{SE} = 5.47 \pm 2.87$, $\chi^2_1 = 3.85$, $P = 0.0498$; Table S2).

We did not find evidence that this pattern of negative kin discrimination was an attempt to reduce inbreeding between targeted females and dominant males. We found that it was relatedness of females to female dominants (not male dominants) that predicted whether they were targeted for eviction. Females were more likely to be targeted if they were more closely related to female dominants (females older than 3 y: GLMM, $\beta \pm \text{SE} = 5.10 \pm 2.65$, $\chi^2_1 = 4.07$, $P = 0.044$; Table S3), but not if they were more closely related to male dominants (males older than 3 y: GLMM, $\beta \pm \text{SE} = 3.69 \pm 2.55$, $\chi^2_1 = 2.09$, $P = 0.15$; Table S3). Behavioral data indicate that females are almost entirely responsible for the attempts at eviction of other females: males rarely attacked females in female-only eviction attempts (GLMM, $\beta \pm \text{SE} = 1.80 \pm 0.56$, $\chi^2_1 = 12.48$, $P < 0.001$; Fig. 3B and Table S4). Previous work indicates that eviction attempts are triggered when the level of reproductive competition in the group is high, not when the potential for inbreeding is high (13), and that both sexes use kin discrimination during mating to avoid inbreeding (12).

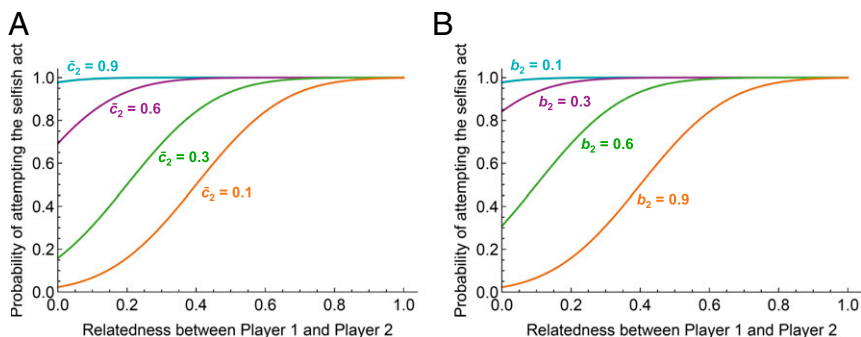

Fig. 2. Impact of model parameters on patterns of kin discrimination. Here we focus on a region of parameter space in which player 1 should carry out the selfish act when unopposed, but in which player 2 may do best to resist (i.e., $b_1 - c_1 - r b_2 > 0$). We show the probability that, at equilibrium, the actor attempts a selfish act, as a function of relatedness, when c_2 is drawn from a normal distribution with specified mean and SD equal to 0.2. (A) Probability that a selfish act is attempted at equilibrium, assuming that $b_1 = 1$, $c_1 = 0.1$, $b_2 = 0.5$, and mean c_2 as specified for the plotted curves. (B) Probability that a selfish act is attempted at equilibrium, assuming that $b_1 = 1$, $c_1 = 0.1$, $c_2 = 0.5$, and b_2 is as shown in the plot.

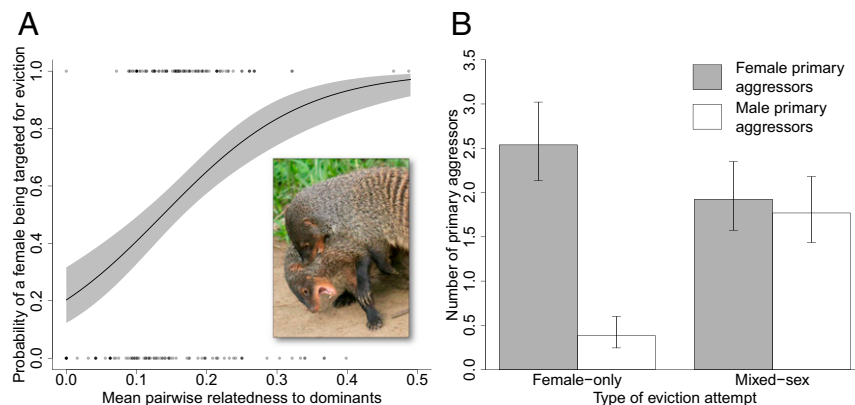

Fig. 3. Negative kin discrimination and sex-specific aggression in banded mongooses. (A) The effect of mean pairwise relatedness to dominants (males and females older than 3 y) on the probability of a female being targeted for eviction ($n = 207$ females in 29 eviction attempts in five groups). The line shows the prediction from the GLMM (\pm SE). (A, Inset) Eviction attempts are highly aggressive and involve biting, chasing, and wrestling (photo courtesy of Dave Seager) (Movie S1). (B) The number of female (gray bars) and male (white bars) primary aggressors in female-only and mixed-sex eviction attempts ($n = 26$ eviction attempts in six groups). The bars show the predictions from the GLMM (\pm SE).

We also did not find evidence for the alternative hypothesis that closer relatives are targeted for eviction because they inflict higher costs on the reproductive success of dominants. Dominant females did not suffer greater reproductive costs when cobreeding with more closely related females. There was no difference in the number of emergent pups to which dominant females gave birth when cobreeding with more closely related vs. less closely related females (GLMM, $\beta \pm$ SE = -0.06 ± 0.12 , $\chi^2_1 = 0.23$, $P = 0.63$; Table S5); nor was there a difference in the proportion of the emergent litter that was assigned maternity to dominant individuals (GLMM, $\beta \pm$ SE = -0.08 ± 0.14 , $\chi^2_1 = 0.27$, $P = 0.60$; Table S5).

Among males, by contrast with females, there was no effect of an individual's mean pairwise relatedness to dominant group members (males and females older than 3 y) on the probability of being subject to an eviction attempt (mixed-sex eviction attempts: GLMM, $\beta \pm$ SE = 0.84 ± 3.08 , $\chi^2_1 = 0.07$, $P = 0.79$; Table S1). We found no evidence of any discrimination as to which males were targeted for eviction (Table S1). There was also no discrimination of any kind when we restricted our analysis to cases where the identity of primary aggressors was known (Table S2) or when we tested the effect of mean pairwise relatedness to same-sex and opposite-sex dominants (Table S3). Unlike the case for female-only eviction attempts, both males and females were primary aggressors in eviction attempts directed at both sexes (GLMM, $\beta \pm$ SE = 1.80 ± 0.56 , $\chi^2_1 = 12.48$, $P < 0.001$; Fig. 3B and Table S4).

Testing Model Predictions

Two specific predictions of the model are (i) that selfish acts will be directed preferentially toward closer relatives only when recipients can resist and (ii) that resistance to selfish acts offered by recipients should decrease as their relatedness to the actor increases. After we developed the model, we tested these predictions. To test the first prediction, we examined how the effect of relatedness varied with the age and weight of potential evictees. Our reasoning was that younger or lighter females should be less able to resist eviction attempts and that the pattern of negative kin discrimination should therefore be more pronounced when eviction is targeted at older or heavier individuals. We found that older females were indeed more likely to be targeted for eviction when more closely related to dominants, but that no such effect of relatedness was apparent for younger females (interaction between relatedness and age: GLMM, $\beta \pm$ SE = 0.008 ± 0.004 , $\chi^2_1 = 5.98$, $P = 0.014$; Fig. 4A and Table S6). The strong overall positive relationship between the probability of being targeted for eviction and relatedness was thus driven almost entirely by the pattern in older females (SI Methods, Fig. S2, and Fig. 4A). A similar interaction was also found between relatedness

and weight (GLMM, $\beta \pm$ SE = 0.03 ± 0.02 , $\chi^2_1 = 5.63$, $P = 0.018$; Table S6). Consistent with prediction i, therefore, negative kin discrimination was restricted to cases in which the targets of eviction were older or heavier and potentially more capable of offering resistance. As predicted by our model, we found no discrimination on the basis of relatedness for cases where the targets of eviction were younger or lighter and therefore likely to suffer high costs of resistance (a high value of \bar{c}_2 ; Fig. 2A).

We found no evidence for the alternative hypothesis that the pattern of negative kin discrimination among older females arises because older, more closely related females inflict higher reproductive costs on dominants (number of emergent pups assigned to dominant female, GLMM, interaction between female cobreeder age and relatedness to dominant female, $\beta \pm$ SE = 0.00002 ± 0.0002 , $\chi^2_1 = -0.07$, $P = 1.00$; proportion of emergent litter assigned to dominant female, GLMM, interaction between female cobreeder age and relatedness to dominant female, $\beta \pm$ SE = -0.00005 ± 0.0002 , $\chi^2_1 = 0.08$, $P = 0.78$; Table S5).

To test further whether negative kin discrimination depends on the capacity of recipients to resist, we examined kin discrimination in cases of infanticide of newborn pups. Between 1 and 12 females reproduce in each breeding attempt (14) and birth is highly synchronized, with pregnant females giving birth on exactly the same morning in 63% of cases (15). Experimental and observational evidence suggests that asynchronous litters are often killed by dominant females (14, 15) and that in asynchronous litters the death of a litter in the first week after birth can be used as a proxy for infanticide (15, 16). In contrast to the pattern of negative kin discrimination in the eviction of adult females, there was no evidence of kin discrimination in cases of presumed infanticide (GLMM, $\beta \pm$ SE = -0.64 ± 2.00 , $\chi^2_1 = 0.10$, $P = 0.75$; Table S7). This is again consistent with our model, which predicts zero or positive kin discrimination where resistance is impossible or prohibitively costly (Figs. 1 and 2A).

To test the second prediction, that resistance to the selfish act should decrease as the recipient's relatedness to the actor increases, we examined the effects of relatedness to dominants (males and females older than 3 y) and age on the probability of females targeted for eviction overcoming efforts to permanently exclude them from the group. After being targeted for eviction, some individuals leave the group, splitting into single-sex cohorts and dispersing separately in cases where males and females are evicted together. Other targeted individuals, however, actively resist eviction: they persist in following the rest of the group, despite being aggressively driven away, until efforts to expel them eventually cease (9). Some attempts at eviction may thus be said to "fail," largely due to sheer persistence on the part of the potential evictees. We predicted, therefore, that the probability of

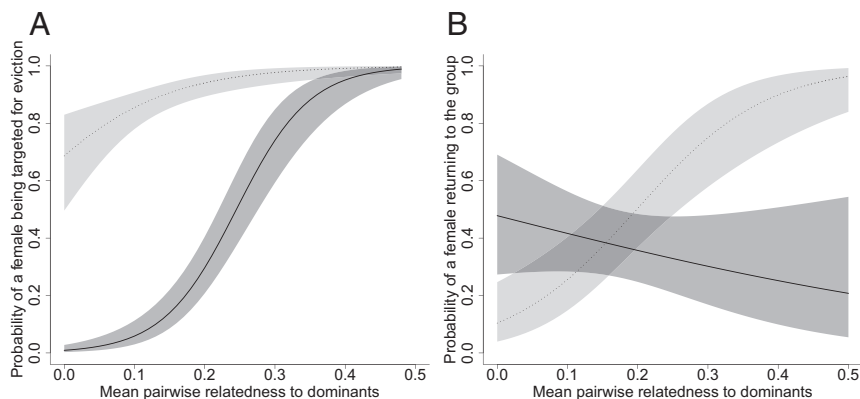

Fig. 4. Patterns of kin discrimination toward recipients capable of offering varying levels of resistance. (A) In eviction attempts, dominants (males and females older than 3 y) exhibit negative kin discrimination only toward older females ($n = 207$ females in 29 eviction attempts in five groups). The lines show the predictions from the GLMM (\pm SE) for younger females (dotted line and area with light shading, 25th percentile of age = 522 d) and older females (solid line and area with dark shading, 75th percentile of age = 1,636 d). (B) Following an attempt at eviction, older females who were more related to dominants (males and females older than 3 y) were less successful in regaining entry to the group ($n = 76$ females in 14 eviction attempts in four groups); this pattern was reversed in younger females. The lines show the predictions from the GLMM (\pm SE) for younger females (dotted line and area with light shading, 25th percentile of age = 446 d) and older females (solid line and area with dark shading, 75th percentile of age = 922 d).

resisting eviction and regaining entry to the group should decline with increasing relatedness to dominant individuals, particularly among older females who are potentially more capable of resisting eviction. There was a significant interaction between the effect of relatedness and the age of targeted females on the probability of regaining entry (interaction between relatedness and age: GLMM, $\beta \pm$ SE = -0.03 ± 0.01 , $\chi^2_1 = 5.96$, $P = 0.015$; Fig. 4B and Table S8). Among older females, individuals that were more closely related to dominants were less likely to regain entry to the group, although this slope was not significantly different from zero (SI Methods, Fig. S3, and Fig. 4B). By contrast, among younger females, more closely related targets were significantly more likely to regain entry (SI Methods, Fig. S3, and Fig. 4B).

Discussion

We have shown in very general terms that where recipients can offer resistance, individuals can gain from targeting selfish acts at closer, rather than more distant, relatives. In the particular case of violent eviction in banded mongooses, this model may therefore explain why dominant females target closer female relatives and why such discrimination is restricted to cases where recipients can offer most resistance. Patterns of resistance, particularly among younger females, deviated from the model predictions, as we discuss in more detail below. Further tests of the model could adopt an experimental approach to manipulate resistance or the costs and benefits of selfishness, which was not possible in our long-term field study.

Whereas our findings offer qualified support for the predictions of our model, it is important to consider alternative explanations for our results. For example, there has been much recent theoretical interest in the possibility that local competition among kin can erode selection for local helping and instead favor indiscriminate harming behavior (16, 17). A prediction of these models is that, across groups or species, rates of aggression may be independent of relatedness (17, 18). However, these models cannot explain the targeting of closer kin for aggression when less closely related, but otherwise equivalent targets are available. A second possibility is that relatedness is correlated with some other factor influencing aggression, such as resource holding potential (RHP) or the level of reproductive competition. For example, in sea anemones, higher aggression among closer relatives has been attributed to their greater similarity in RHP (5). In banded mongooses, there is no evidence that related females are of higher RHP or represent more of a reproductive threat. In fact, younger females (with lower RHP and who reproduce less often) are more

likely to be targeted for eviction overall, regardless of relatedness (Fig. 4A). Moreover, our data show that dominant females do not suffer greater reproductive costs when they co-breed with more closely related females (Table S5). Our findings also cannot be explained as a nonadaptive side effect of selection to discriminate between species of heterospecific competitor, which has been suggested to explain negative kin discrimination in polyembryonic wasps (6).

Finally, it has been suggested that targeting relatives for eviction could be part of an adaptive forced dispersal strategy by breeders to maximize metapopulation fitness in a structured population (13). In a previous study we did not find support for this hypothesis as a predictor of eviction at a group level (13). Moreover, it is difficult to reconcile this idea with our observations of negative kin discrimination within a given eviction attempt. In classic models such as that of Hamilton and May (19), dispersal entails direct costs for individuals who leave their natal patch, but is nevertheless favored because it reduces local competition among kin. Because offspring value their own survival more than that of their siblings, whereas parents value all their offspring equally, offspring favor a lower dispersal rate than do their parents, and selection can therefore favor forced eviction of young (20–22). However, eviction by an adult of unrelated young offers equal benefits, in terms of reduced local competition, to eviction of related young, without inflicting the direct costs of dispersal on a relative. Hence, where adults can choose whom to evict, local kin competition alone cannot explain why they should preferentially target more related over less related young for expulsion. There may be other asymmetries associated with the forced dispersal of kin vs. nonkin, deriving, for example, from variation in local competitive ability or variation in the bet-hedging benefits of dispersal (23), but the effect of such variation on forced dispersal in heterogeneous groups has been little explored theoretically or empirically (13, 24). In banded mongooses, there is no evidence that closer kin compete more intensely (Table S5) or that forced dispersal of kin yields bet-hedging benefits.

We predicted that resistance to eviction should decrease with increasing relatedness to dominants. Contrary to this prediction, among younger females, closer relatives were more likely to regain entry to the group than older or less closely related females (Fig. 4B). This result runs directly counter to our assumption that these females are weaker and less able to force their way back into the group and suggests that factors other than strength or the costs of resistance may underlie the pattern by which younger females return to the group. For example, following eviction, dominants may voluntarily readmit closely

related, younger females that would otherwise fare very badly outside the group. The negotiation process by which females regain entry to the group may thus be more complex than the simple two-step sequence of eviction and resistance assumed by our model. Whereas our analysis shows that even a two-step game can yield results that diverge from classical predictions, it is likely that many negotiations in family groups may be modeled better as a sequence of three or more steps, something we have not attempted here.

Negative kin discrimination was evident only in eviction attempts of females. In males we found no relationship between relatedness and the probability of being targeted for eviction. This difference between the sexes could reflect differences in the direct fitness incentive for males and females to retain group membership, which in our model is represented by the parameter b_2 (Fig. 1). Females gain greater direct fitness from group membership (i.e., higher b_2) than males because there is little or no reproductive suppression, and most females breed from the age of 10 mo (11, 25). In males, by contrast, most individuals are excluded from mating by the two or three oldest males within the group (10). In our model, low values of b_2 favor little or no kin discrimination (Fig. 2B). A relatively low value of b_2 in males compared with females may explain why males sometimes disperse voluntarily as a group, whereas females are invariably forced to leave after being subject to violent attack (7, 13).

More generally, our model shows that incorporating even very simple forms of behavioral anticipation can radically change the predictions of kin selection theory. Where such anticipation is possible, higher relatedness can lead to outcomes that are less favorable on average for all those involved, because the threat of resistance or punishment of selfish behavior is less credible between relatives than between unrelated individuals. Many empirical studies have shown that animals are in fact capable of adjusting their behavior according to the anticipated responses of their social partners in a range of contexts. Examples include signaling systems (26), negotiation over care of offspring (27), restraint in competitive growth (28), and audience effects (29). However, few have considered the possibility that this kind of anticipation might lead to less cooperative outcomes among closer kin. An example comes from economic studies of human behavior in the context of joint-liability group lending, which have found higher rates of loan default when there are more relatives within a group (30, 31), leading to barring of remaining group members from future borrowing. This pattern has been attributed to the difficulty of group members imposing penalties on relatives to enforce repayment (32, 33). Our results suggest that similar patterns might also occur in the behavior of other species and that the influence of kinship on aggression and cooperation within animal groups may be considerably more subtle and variable than predicted by classical kin selection theory.

Methods

Study Population and Data Collection. Data were collected from 15 groups of banded mongooses living on the Mweya Peninsula, Queen Elizabeth National Park, Uganda (0°12'S, 27°54'E), between September 1997 and October 2015. For further details of habitat and climate, see ref. 8. Groups were visited every 1–3 d to record group composition, life history, and behavioral data. Individuals were easily identifiable by unique shave markings on their back and were regularly trapped to maintain these markings (34). On first capture a 2-mm skin sample was collected from the end of the tail for genetic analyses. For details of genetic analyses and calculating relatedness see *SI Methods*. Individuals were trained to step onto portable electronic scales to obtain weight measurements. The research was conducted with permission from Uganda Wildlife Authority and Uganda National Council for Science and Technology, and all methods were approved by the Ethical Review Committee of the University of Exeter.

We observed the attempted eviction of 405 individuals from eight groups in 44 eviction attempts. Eviction attempts were conspicuous, violent events and easy to recognize. We defined an eviction attempt to have occurred if one or more individuals left their group for at least 1 d following a period of intense aggression toward themselves or other group members (13, 35, 36). In 21 of 44 eviction attempts all targeted individuals rejoined their group; in

14 attempts some targeted individuals returned whereas others did not; and in 9 eviction attempts all targeted individuals dispersed.

Statistical Analyses. Statistical analyses were performed in R 3.3.0 (37). We used GLMMs with a binomial error structure using a logit-link function, or a Poisson error structure using a log link function, in the “lme4” package (38). Poisson models were checked for overdispersion (39). In all analyses, we assessed the significance of each fixed effect by comparing the likelihood ratio of the maximal model to that of the model without the fixed effect (38). We present parameter estimates and SEs from maximal models, rather than removing nonsignificant fixed effects due to problems associated with stepwise model reduction (40). We did, however, remove nonsignificant interactions to allow the significance of the main effects to be tested (41).

i) Negative kin discrimination in banded mongooses. Models were fitted to male and female data separately because not all eviction attempts involved males. We considered adult females over 10 mo old, because females younger than 10 mo are unlikely to be regular breeders and are rarely evicted (7, 11, 25). We fitted whether or not a female was targeted for eviction during an eviction attempt as the binomial response variable. We included mean pairwise relatedness to dominants in the group, which we defined as males and females over 3 y of age, as a fixed effect. We use this age criterion for social dominance throughout because, in both males and females, individuals over 3 y of age are more likely to breed, have higher fertility, and appear to be socially dominant (7, 10, 14, 42). In males there is a clear age-based dominance hierarchy, evident during estrus (10, 42). In females, experimentally suppressing reproduction in older females (>3 y) results in failure of the communal litter, whereas suppressing reproduction in younger females (<3 y) does not (14). Older females also breed more frequently (7, 11) and produce larger litters (43). Age (days), pregnancy status (pregnant or not pregnant), mean nonpregnant weight (grams) in the 60 d before the eviction attempt, mean rainfall (millimeters) in the 30 d preceding the eviction attempt, and group size (number of individuals over 6 mo) were included as additional fixed effects. We controlled for repeated measures of individuals, eviction attempts, and groups by including these terms as random intercepts and fitted the model to data on 207 females in 29 eviction attempts in five groups. To examine which males were targeted for eviction we considered adult males over 1 y old, because males under 1 y do not sire young (7, 42), and fitted whether or not a male was targeted for eviction during a mixed-sex eviction attempt as the binomial response variable. We included the same fixed and random effects as in the female model but, instead of pregnancy status, we included the male's breeding status (whether or not the male had been observed mate guarding or had sired pups in the current breeding attempt) and fitted the model to data on 177 males in 15 eviction attempts in five groups.

Aggressive interactions between targeted individuals and other group members during eviction attempts were numerous, but systematic data on the identity of aggressors were difficult to record. However, since 2000 we have noted ad libitum the identity of individuals that were notably more aggressive than other group members toward potential evictees. Data on 86 of these primary aggressors were available for 26 eviction attempts. To investigate the relationship between the sex of primary aggressors and the sex of individuals targeted for eviction we fitted the number of primary aggressors in each eviction attempt as the Poisson response variable and included the sex of the primary aggressors, the type of eviction attempt (female only or mixed sex), and the interaction between these two variables as fixed effects. We included group identity and eviction attempt as random intercepts and fitted the model to 26 eviction attempts in six groups. See *SI Methods* for details of analyses of negative kin discrimination by primary aggressors, to avoid inbreeding or as a response to reproductive competition.

ii) Testing model prediction i: The selfish act will be directed preferentially toward closer relatives only when recipients can resist. We repeated the original analysis investigating negative kin discrimination among females in eviction attempts, but included two-way interactions between female relatedness to dominants and age (days) and female relatedness to dominants and weight (grams). Other fixed and random effects were as in the original analysis. We fitted this model to data on 207 females in 29 eviction attempts in five groups.

To test further model prediction *i*, we examined kin discrimination in cases of infanticide of newborn pups. Infanticide is known to occur in this system, but is difficult to observe directly as it typically occurs in the den. In asynchronous litters, infanticide appears to be common because early life pup mortality is strongly dependent on the pregnancy status of other females in the group (14, 15). Pups that are born early in asynchronous litters almost always die in the first few days after birth, whereas pups born last almost

always survive (15). Between November 1997 and October 2015, we recorded the order in which each female gave birth in an asynchronous litter (i.e., if she gave birth first, in the middle, or last) and whether any of her pups survived the first week after birth. Following ref. 15, we used the presence or absence of “babysitters” (adults left at the den to guard newly born pups) to measure patterns of early life litter mortality. Specifically, to determine the survival of an individual female’s pups, we considered only females who gave birth early relative to the rest of the breeding females and for which the failure of a specific female’s litter could be detected using cessation of babysitting (i.e., we did not consider females who gave birth when babysitting of other early-birthing females’ pups was still ongoing). A female’s litter was determined to have survived the first week after birth if there were still babysitters left 7 d after birth or if she was retrospectively assigned maternity to at least one emergent pup from the communal litter following genetic analysis. We observed 166 females that fitted the criteria outlined above, who gave birth to 120 asynchronous litters in 15 groups. Where none of the female’s pups survived the first week after birth, they were assumed to have been subject to an infanticidal attack. To test whether pups are more likely to be targeted for infanticide when mothers are less related to female dominants in the group, we fitted whether or not each female’s pups survived the first week after birth as the binomial response variable. We included the mother’s mean pairwise relatedness to female dominants older than 3 y of age, mother’s age (days), group size, and rainfall (millimeters) in the 30 d before birth as fixed effects. We controlled for repeated measures of mothers, litters, and groups by including these terms as random intercepts

and fitted the model to data on 57 females giving birth to 50 communal litters in 11 groups.

iii) Testing model prediction ii: Resistance to the selfish act offered by recipients should decrease as their relatedness to the actor increases. We fitted whether or not a female over 10 mo old that was targeted for eviction overcame efforts to permanently exclude her from the group as the binomial response variable. We considered only eviction attempts where some evictees were allowed to return and others were not due to problems with fitting a binomial model to outcomes that are exclusively successes or failures. We included mean pairwise relatedness to dominants in the group, age (days), and the interaction between these two variables as fixed effects. We were unable to include additional fixed effects in the model due to problems with model convergence. We controlled for repeated measures of individuals, eviction attempts, and groups by including these terms as random intercepts and fitted the model to data on 76 females in 14 eviction attempts in four groups.

ACKNOWLEDGMENTS. We are grateful to Uganda Wildlife Authority and Uganda National Council for Science and Technology for permission to carry out our research and to the Wardens of Queen Elizabeth National Park for logistical support. We thank Francis Mwanguhya, Solomon Kyambulima, Kenneth Mwesige, Robert Businge, Solomon Ahabyona, Emily Otali, Corsin Müller, Neil Jordan, Bonnie Metherell, Roman Furrer, and David Jansen for assistance in the field. Thanks to Bram Kuijper, and three anonymous reviewers for comments on the manuscript. Funding was provided by Natural Environment Research Council Grant NE/J010278/1 (to M.A.C. and A.J.Y.) and European Research Council Grant 309249 (to M.A.C.).
